

Analogue measurements with Emiscope

Distortion-free measurements with Time Resolved Emission

Presented by Frank Zachariasse
NXP Failure Analysis

Developed by Keith Sarault and Gerben Boon
August, 2008

Outline

- ▶ Traditional methods for FA of Analogue circuits
- ▶ Why use Emiscope for FA of Analogue circuits ?
- ▶ Emiscope : Limitations for analog measurements
- ▶ Improved measurement set-up
- ▶ Case study : Fault localisation in a Class-D amplifier

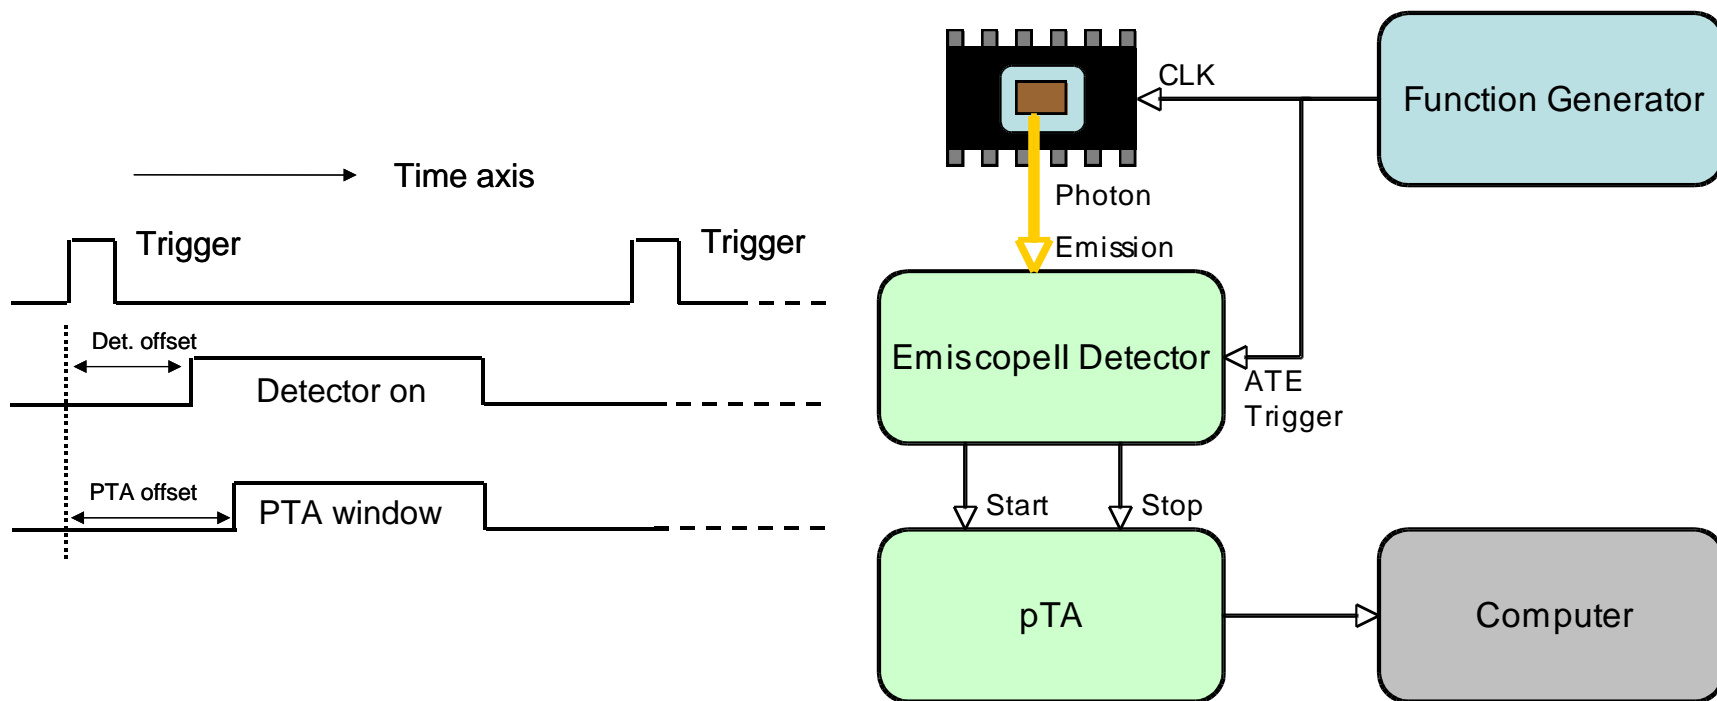

Traditional methods for Analogue FA

- ▶ Need to trace signals, check which block is failing
 - Microprobing + Oscilloscope
 - Electron Beam tester
- ▶ Problems :
 - Need to remove passivation, perhaps make probe pads
 - Time consuming, risk damaging sample
 - Difficult when > 2 metals in analog circuit
 - Power supply tracks block access to the signals
 - Probing can load signals, distort results
- ▶ Therefore : Prefer Non-invasive, Fast, Safe method

Why use Emiscope ?

- ▶ Signals collected by 'viewing' only : Not invasive
- ▶ Less risk to damage the circuit : no "slipping needles"
- ▶ Access to every transistor : All signals can be measured
- ▶ Our findings :
 - Traditional method, probing : 4 hours / sample to trace signal
 - Emiscope method : 20 minutes / sample
- ▶ **Problem : Non linear distortion of the signal, with normal set-up**

Emiscope – Normal set-up

- ▶ ATE triggers the Emiscope photon detector
- ▶ Same trigger also starts the PTA
- ▶ PTA and Photon detector always on at the same time, synchronous

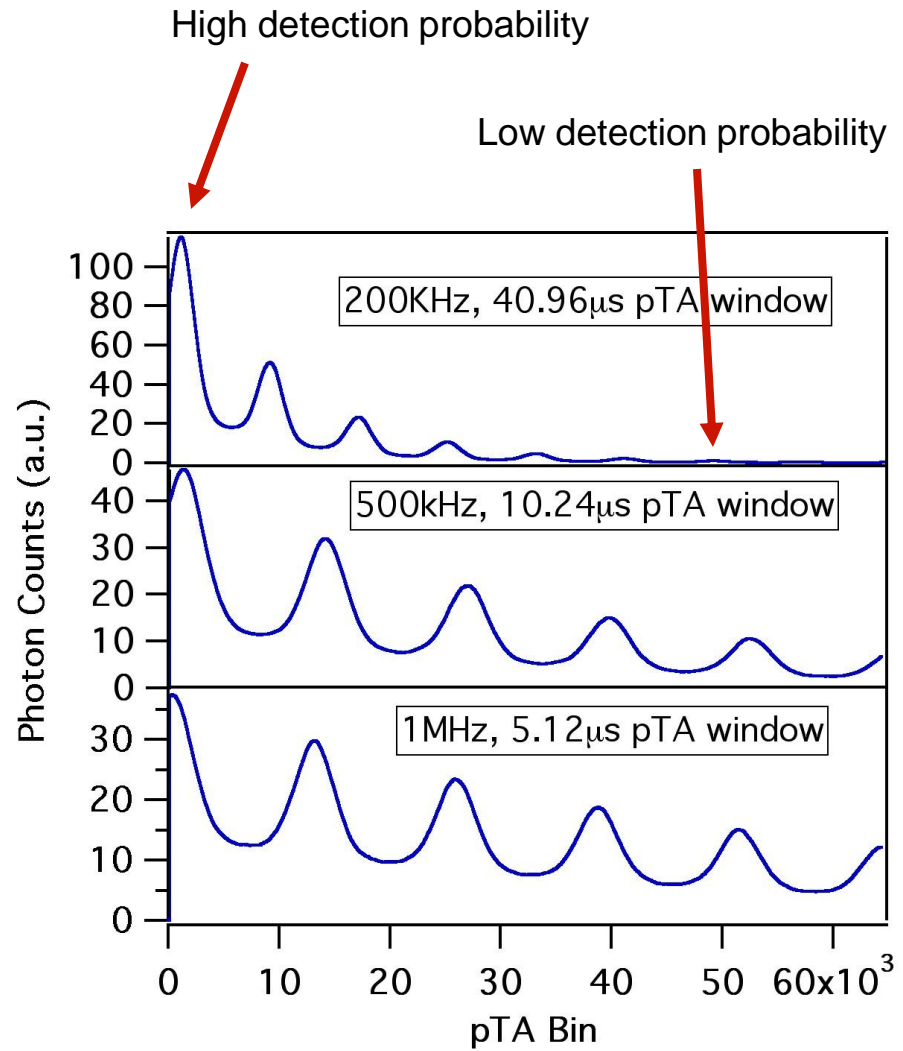

Using normal setup on analog circuit

- ▶ Class A amplifier, NMOST
- ▶ NMOST, 140 nm technology
- ▶ Constant bias current
- ▶ Therefore constant emission
- ▶ Sine wave signal used as input

Sine Wave :

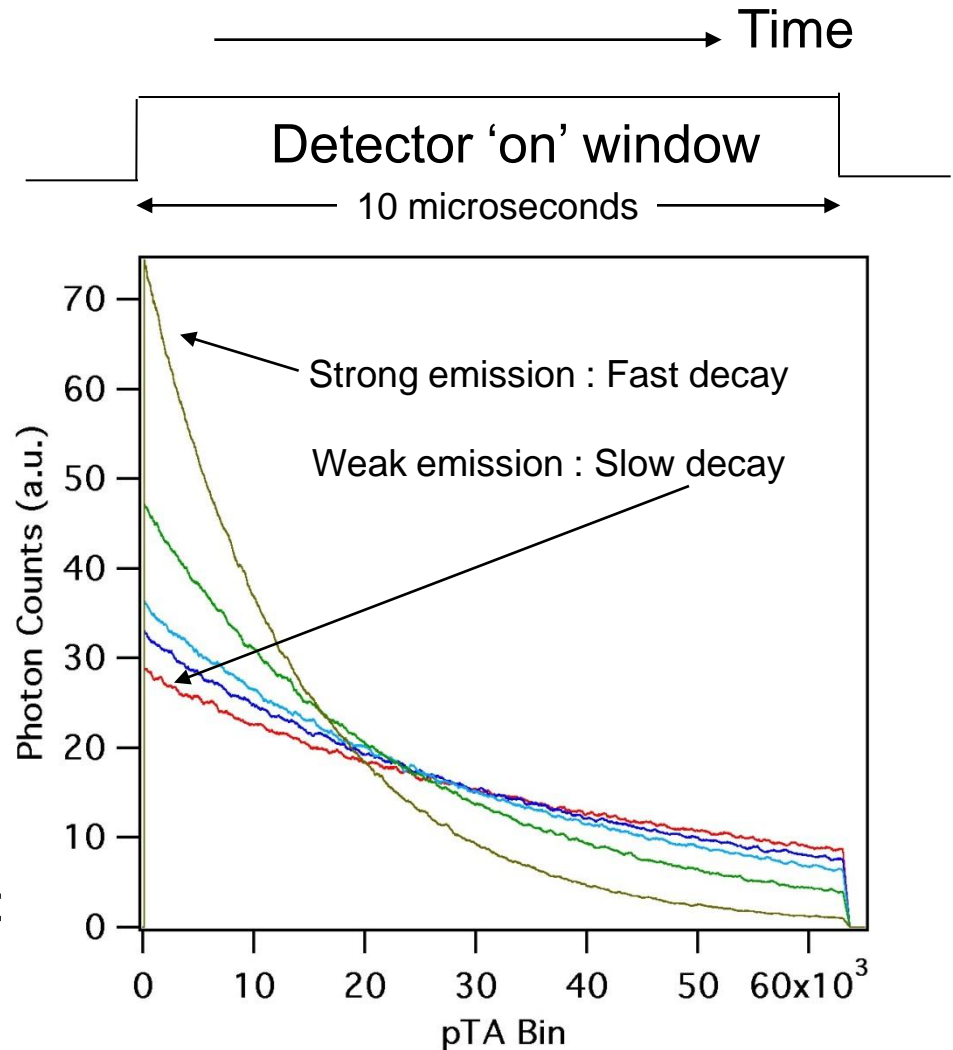

1.3V offset

0.6V p-p swing

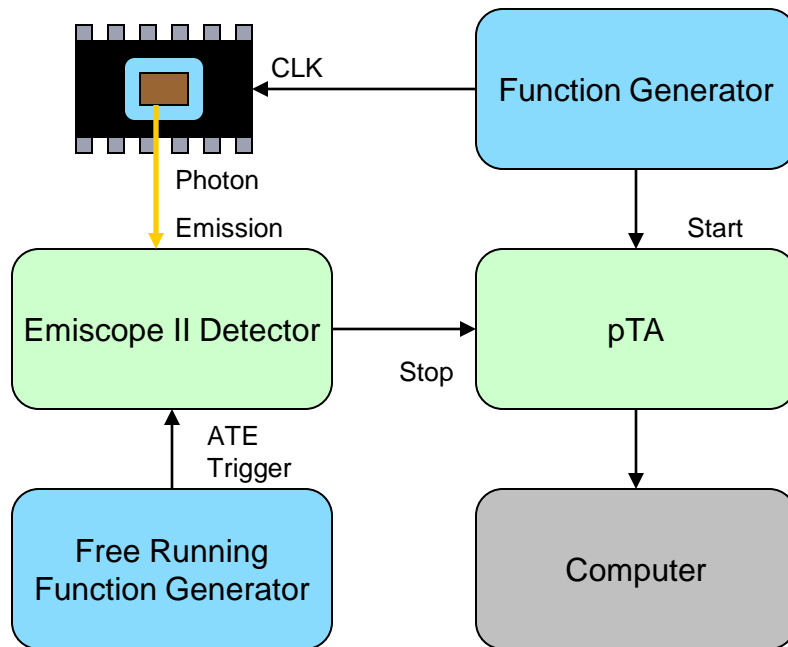

Cause of distortion

- ▶ When detector is switched 'on' :
 - Only one photon detected
 - After that : Detector 'dead'
 - Reset detector with new trigger
- ▶ Therefore :
 - Early in window : High probability that detector still active
 - Late in window : Detector probably already triggered
- ▶ This leads to non-linear distortion :
Decay depends on signal strength

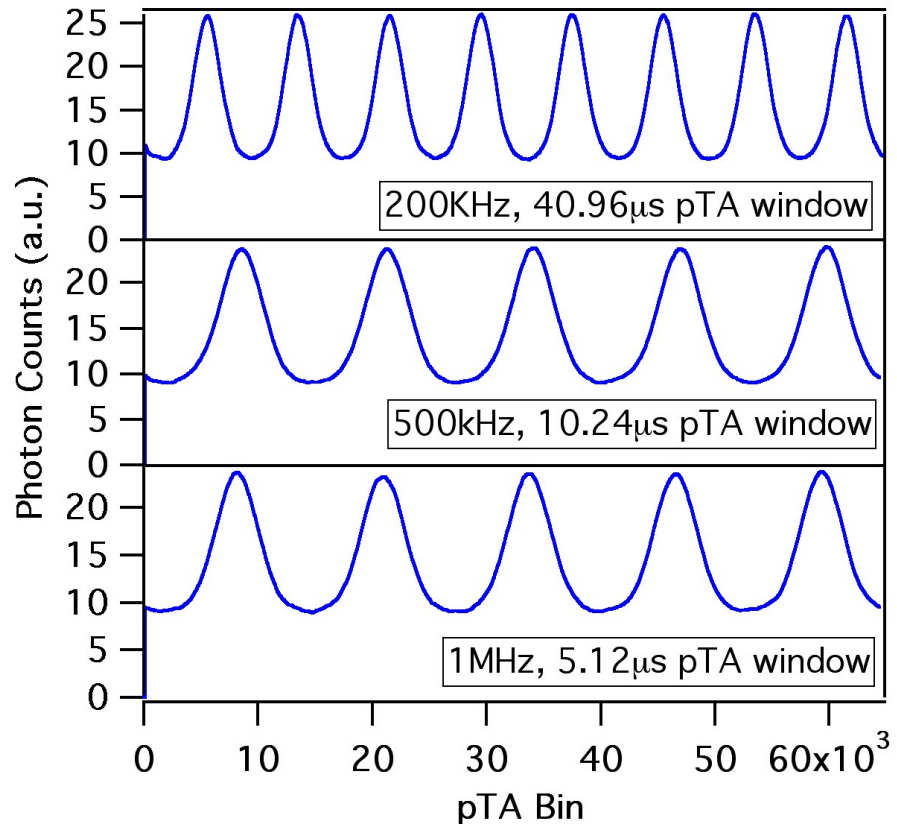

Constant photoemission

Alternative set-up for Analog measurements

Class "A" amplifier - again

Detector 'window' is now ASYNCHRONOUS to pTA window
This gives constant detection probability across the window

Quantitative measurement

Sine Wave :

1.3V offset

0.6V p-p swing

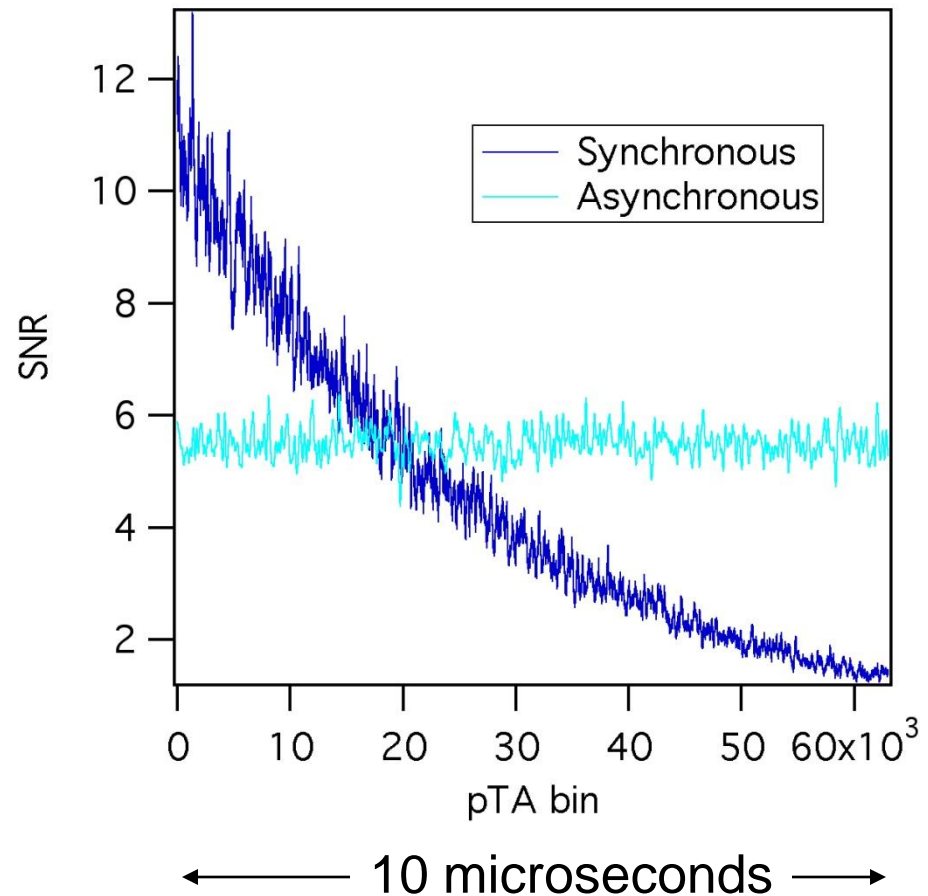

Emission is a non-linear function of V_g

Correcting sine wave for exponential emission gives a good fit

Comparison of Signal:Noise Ratio

- ▶ Asynchronous method has a constant SNR across pTA window
- ▶ Normal, synchronous method has SNR that drops off
- ▶ You lose some signal at the start of the window
- ▶ But, you gain a lot at the end
- ▶ Overall, acquisition is much faster

Case study : Qualification failure

- ▶ Analogue Class D audio amplifier
- ▶ 1 μm “ABCD” technology
 - Bipolar, CMOS, DMOS
 - SOI wafer
- ▶ Failed DHTL test, 1000 hours
- ▶ 2 audio channels (L & R)
- ▶ One channel failed

Output driver transistors

Convert Analog input
To PWM output

Ref 08fa2733

Class D amplifier – Basic principles

Analog measurement of square wave

Digital driver

Current square wave

Period : 3 μ s

Root Cause - deprocessing

- ▶ “Falling” current source had short circuit
- ▶ Caused by Polysilicon residue
- ▶ Shown by HF strip and SEM inspection

Conclusions

- ▶ How to use Emiscope to measure analog waveforms ?
 - Make detector window Asynchronous to pTA window
 - This eliminates the sensitivity decay for analog measurements
 - Also provides constant Signal:Noise across the whole measurement
- ▶ Main application : Localize failing site by signal tracing
- ▶ Compare with 'known good chip' to find faulty block
 - Don't care too much about exact quantitative measurement
- ▶ Case study demonstrates effectiveness
